CASE REPORT

An 88-year-old female with a previous history of retinopathy requiring treatment with Adiro® (acetylsalicylic acid) presented with jaundice, pruritus and right upper quadrant pain. An abdominal ultrasound revealed multiple stones in the common bile duct (CBD). Adiro® was stopped five days before ERCP. ERCP confirmed the presence of multiple stones in the CBD, which were extracted after performing a sphincterotomy. Four days later the patient presented with melena and anemia (hemoglobin of 8.9 g/dL).

Post-sphincterotomy bleeding was suspected. A new ERCP revealed an adherent clot at the level of the papilla with active oozing bleeding. After the clot was removed using a polypectomy snare (Fig. 1) a prominent red vessel with active bleeding was seen underneath. Hemostasis was achieved with the application of one HemoClip (Fig. 2). The patient did not require blood transfusion and was discharged 48 hours later. There was no further bleeding and the patient did not develop pancreatitis.

DISCUSSION

Approximately one-half of bleeding complications occur immediately after sphincterotomy; a delay of 24 hours up to several days is observed in other patients (1). Hemostasis can be achieved, by precise placing of a single or more hemoclips at the bleeding site. However, published cases of this treatment are limited (2,3). Clips may be difficult to apply with the side-viewing endoscope in the setting of active bleeding. In addition, clips may be inadvertently applied to the pancreatic orifice with the associated risk of pancreatitis.
