Department of Surgery, Hospital General Reina Sofía, Murcia, Spain

CASE REPORT

A 55-year-old patient presented with ethanolic cirrhosis (CHILD B9) and hemodynamic instability (heart rate: 112 bpm, blood pressure: 83/62) from massive upper gastrointestinal bleeding (UGIB). Upper gastrointestinal endoscopy (UGIE) revealed active bleeding from esophageal varices. As sclerotherapy and band ligation failed to provide hemostasis; the decision was made to use a Sengstaken balloon (SB). The balloon was insufflated with 300 ml for the gastric channel and 200 ml for the esophageal channel. X-rays after insufflation showed the gastric balloon at the distal esophagus. A repeat UGIE procedure showed a laceration at the lower third of the esophagus. A CT scan revealed pneumomediastinum (Fig. 1A). Given his clinical instability, the patient was operated on immediately, and an 8-cm longitudinal esophageal rupture was found in the lower third (Fig. 1B), which underwent primary suture repair. She died after five days from hepatorenal syndrome.

DISCUSSION

UGIB from esophageal varices in the setting of portal hypertension is a high mortality situation. Treatment with vasoactive drugs and endoscopic ligation is effective in 76-96% of cases (1). SB is an effective salvage option when the above fails to temporarily control bleeding (effectiveness up to 90%) (2), but morbidity and mortality remain high. Major complications include: bronchoaspiration, rupture, and esophageal necrosis (2).

SB placement must be checked with auscultation to detect air insufflation within the gastric cavity, misplacement being the primary cause of esophageal rupture.

Surgery is the treatment of choice for esophageal rupture. Conservative endoscopic management with Ovesco clips and self-expandable stents has been described for smaller tears (< 10 mm) in the absence of sepsis (3).
