Effects of a high-fat meal on postprandial incretin responses, appetite scores and ad libitum energy intake in women with obesity

Efectos de una comida rica en grasas en la respuesta posprandial de las incretinas, del apetito y en la ingestión de energía ad libitum en mujeres con obesidad

Abstract

Background: Considering the possible role of triglycerides (TG), glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) in the regulation of appetite, this study aimed to compare high fat meal-induced response of GIP and GLP-1, appetite scores and ad libitum energy intake in women with obesity, according to postprandial increment in triglyceridemia (ΔTG).

Methods: Thirty-three no-diabetic women (BMI = 35.0 ± 3.2 kg.m⁻²) were divided into two groups: Group with ΔTG ≤ median were called “Low TG change -LTG” and ΔTG > median, “High TG change - HTG”. Plasma concentrations of GIP, GLP-1 and appetite sensations were measured prior to, and every 30 min for 180 min after ingestion of a high-fat breakfast. An ad libitum lunch was served 3 h after the test meal.

Results: The AUC incrementalGIP were significant lower in HTG vs. LTG group (p = 0.03). The same was observed for GIP levels at 150 min (p = 0.03) and at 180 min (p < 0.01). Satiety was lower in HTG at 120 min (p = 0.03) and 150 min (p < 0.01). The AUC totalGLP1 were similar between groups and there were no between-group differences for the GLP-1 at each time point. Ad libitum food intake were also similar between groups.

Conclusions: The HTG group exhibited differences in satiety scores and lower postprandial secretion of GIP, however with no impact on ad libitum food intake in short term.

Resumen

Introducción: teniendo en cuenta las posibles acciones de los triglicéridos (TG), el glucosa-dependiente inesulinotrópico polipéptido (GIP) y del glucagon-like peptide-1 (GLP-1), en la regulación del apetito (hambre y saciedad), este estudio tuvo como objetivo comparar la respuesta posprandial inducida por una comida rica en grasas en los niveles del GIP y GLP-1, en el apetito y en la ingestión de energía ad libitum en mujeres con obesidad, clasificadas de acuerdo con el aumento de la triglicericidemia posprandial (ΔTG).

Métodos: treinta y tres mujeres sin diabetes (IMC = 35.0 ± 3.2 kg.m⁻²) fueron clasificadas en dos grupos: grupo con ΔTG < mediana (“bajo cambio en los TG - LTG”) y grupo ΔTG > mediana (“alto cambio en los TG-HTG”). Los niveles plasmáticos del GIP, GLP-1 y del apetito fueron evaluados antes y cada 30 minutos durante 180 minutos después de la ingesta de un desayuno rico en grasas. Un almuerzo ad libitum fue servido 3 horas después del desayuno.

Resultados: el área bajo la curva (AUC) del aumento del GIP (AUC aumentGLP1) fue significativamente menor en el grupo HTG vs. LTG (p = 0.03). Lo mismo se observó para los niveles del GIP en los 150 minutos (p = 0.03) y en los 180 minutos (p < 0.01). La saciedad fue menor en el grupo HTG en los 120 minutos (p = 0.03) y en los 150 minutos (p < 0.01). La AUC totalGLP1 fue similar entre los grupos y no hubo diferencias entre ellos para los niveles del GLP-1 en los tiempos evaluados. La ingesta alimentaria ad libitum también fue similar entre los grupos.

Conclusiones: el grupo HTG presentó diferencias en la saciedad y menor secreción postprandial del GIP, sin embargo, sin impacto en la ingesta de alimentos ad libitum en el corto plazo.

INTRODUCTION

The homeostatic mechanisms regulating food intake rely on a neuroendocrine system that involves peripheral and central signaling. The peripheral gastrointestinal signs consist of a series of peptides that are produced in response to food intake and modulate hunger and satiety (1). There is growing evidence to suggest that glucagon-like peptide-1 (GLP-1) is one of the mediators of the post-meal satiety response. The main mechanism of satiety exerted by GLP-1 is related to the “fuel brake”, which slows down gastric emptying (2-4). Previous studies have shown that peripheral GLP-1 infusion increases satiety and reduces hunger in a dose-dependent way (3). The underlying mechanisms of action combine slow gastric emptying with direct effects on central nervous system (2). However, these effects are impaired in the obesity and individuals with obesity exhibit attenuated postprandial GLP-1 secretion in comparison to normal-weight controls, which may harms food intake regulation (5-7).

Importantly, most studies evaluating the role of GLP-1 in hunger and satiety have employed peripheral infusion of this hormone, which elevates the serum GLP-1 levels to supraphysiological values, and in these conditions it increases satiety and reduces hunger and energy intake in the short term (8-10). However, gaps in the knowledge of the role of this hormone in appetite modulation in a physiological way, that is, secondary to food intake, still exist, especially in obesity.

In contrast, whether glucose-dependent insulinotropic polypeptide (GIP) has a role in appetite modulation remains unclear. Raben et al. (1994) (11) showed that a higher postprandial GIP response to a high-fat meal were seen in women after weight loss compared to normal-weight controls, and the authors suggest that GIP may promote hunger and excessive food intake. Other studies have founded that postprandial GIP response was inversely related to the subsequent feeling of satiety (5,12,13). On the other hand, positive (14) or neutral (9,10,15) correlation between postprandial GIP and satiety were also observed.

Added to this, evidences in animal studies suggests the involvement of the TG, which are markedly elevated after a high-fat meal, in stimulate hypothalamic peptides known to increase feeding (16-19), and the hyperphagia after a high-fat meal is preceded by a marked increase in circulating TG levels (19).

In this context, the primary aim of the present study was to compare the response of GLP-1 and GIP and the ad libitum energy intake to a standardized high-fat test meal in women with obesity classified according to the change in plasma TG after this meal. We also wanted to examine the relationship between postprandial GLP-1, GIP and TG responses with subjective appetite regulation (hunger and satiety) and ad libitum energy intake.

MATERIALS AND METHODS

STUDY DESIGN AND SUBJECTS

This is a transversal clinical study. Thirty three women with obesity (BMI 30.0-39.9 kg.m⁻²) between the ages of 20 and 45 years were recruited by posters in public places, e-mail and radio programs. None of the subjects used oral hypoglycemic agents, contraceptives and/or hormones, or anti-psychotic with drugs (washout of 3 months); had been diagnosed with diabetes mellitus, hypertriglyceridemia, thyroid dysfunction, hormone disorders; infections diseases or eating disorders; did not like the foods used in the study (bread, margarine, cheese, whole milk, pasta, tomato sauce and ground meat); had undergone nutritional monitoring during the previous 3 months; were pregnant or nursing or were in a menopausal period.

To compare the role of change in circulating TG after a high-fat meal in the postprandial response of GLP-1 and GIP and the ad libitum energy intake, women were classified in two groups according to their TG response after this meal. The median was used as a cutoff point of the postprandial change in TG levels: ∆TG in % = (TG at 180 min-TG at 0 min) x 100 / TG at 0 min. Group ∆TG < median were called “Low TG change - LTG” and ∆TG > median, “High TG change - HTG”.

The study was approved by the Research Ethics Committee of University of São Paulo, Ribeirão Preto Medical School (process number 4618/2009). The patients received 2 consent forms for signature, one before and the other after the study. Only after the study the women were informed that ad libitum food intake would be quantified, thus preventing them from being influenced by this information regarding the amount of food to be consumed.

HIGH-FAT MEAL

On each test day, patients arrived in the research unit in the morning after a 12 h overnight fast. A standardized, fixed energy high-fat breakfast (50 g of french bread with 15 g of margarine and 20 g of cheese and 150 ml whole milk; energy 414 kcal with 50% calories from fat, 35% from carbohydrates and 15% from protein) was then served, and they were instructed to eat all the food offered. Previous studies with high-fat meals also used this same percentage of energy from fat (20,21). Our aim with the high-fat meal was to elicit a sharp rise in the TG levels and stimulate physiological GIP and GLP-1 secretion (22,23).

AD LIBITUM ENERGY INTAKE

The ad libitum meal (lunch) were offered three hours after breakfast and consisted of pasta bolognese. The preparation of the pasta and sauce was standardized and rigorously applied on each day of administration. Each ad libitum meal consisted of 1,900 g (energy density 1.22 kcal.g⁻¹) in order to make participants eat to their satisfaction, without being concerned about food availability and also to avoid variations in the quantity of food offered to each individual, which could interfere in the food intake. Each individual ate alone with no time restriction. The quantity of pasta consumed was evaluated by the difference between the starting amount and the leftovers on the pan and the plate.
**BIOCHEMICAL ANALYSES**

Venous blood was drawn through an indwelling antecubital cannula into syringes. Blood was collected into tubes containing sodium fluoride and EDTA for the analysis of plasma glucose concentrations, in tubes containing clot activator and gel separator for insulin and TG, and in tubes containing EDTA and anti-DPP-IV protease inhibitor (10 µL.mL⁻¹ of blood) for the GIP and GLP-1. All blood samples were kept in ice until centrifugation at 3500rpm for 15 minutes at 4 °C, and serum and plasma samples were stored at -70 °C until analysis.

The analyses were performed at 0 (fasting), 30, 60, 90, 120, 150, and 180 min (this latter period was considered as preprandial, because it occurred before the ad libitum meal). The times selected for analysis of the postprandial curve of GIP and GLP-1 were adapted from the methodology proposed by Verdich et al. (2001) (5), which were also similar to the times used in other studies that described/evaluated postprandial curves of these hormones (24,25).

Total GIP and GLP-1 were determined by the Luminex™ xMAP methodology, by means of the kit GIP and GLP-1-HGT-68k (Millipore®); sensitivities were 0.2 and 5.2 pg.mL⁻¹, respectively, and the CV values were 3.7 and 8.7%, respectively. TG was quantified by the endpoint enzymatic method, by employing the kit Triglycerides Liquiform (Labtest®); sensitivity and CV were 0.99 mg.dL⁻¹ and ≤ 5%, respectively.

Glucose was analyzed by the endpoint photometric method (Glucose PAP Liquiform), with the aid of the kit Glucose PAP Liquiform (Labtest®); the sensitivity and the coefficient of variation (CV) were 0.32 mg.dL⁻¹ and 3.0%, respectively. Insulin was determined by the Luminex™ xMAP methodology, using the kit insulin-HGT-68k (Millipore®); sensitivity and CV were 1.1 µU.mL⁻¹ and 7.3%, respectively. TG was quantified by the endpoint enzymatic method, by employing the kit Triglycerides Liquiform (Labtest®); sensitivity and CV were 0.99 mg.dL⁻¹ and ≤ 5%, respectively.

**ASSSESSMENT OF HUNGER, SATIETY, PREFERENCE AND PALATABILITY**

Previously validated 100-mm visual analogue scales (VAS) were used to assess hunger (“How hungry do you feel now?”) and satiety (“How full/satisfied do you feel now?”) (26). Moreover, after meal, the participants were asked to fill in 100-mm VAS to evaluate preference (“How much do you like pasta bolognese?”) and meal palatability (“How tasty are this pasta?”).

**SAMPLE CHARACTERIZATION**

**Anthropometric and body composition analysis**

Body weight (kg) and height (m) were measured to calculate the body mass index (BMI, in kg.m⁻²). Body composition (fat mass and fat free mass) was evaluated by bioelectric impedance analysis (Biodynamics 450 Bioimpedance Analyzer). These measures were taken at the beginning of the study, in a fasting state.

**STATISTICAL ANALYSIS**

The linear regression model with mixed effects (random and fixed effects) was employed to evaluate the differences in biochemical parameters and appetite between the groups at each time, as well as the difference between times within the same group. This methodology assumes that the residues have normal distribution, with mean 0 and constant variance σ². When this assumption was not verified, the response variable was transformed with the aid of the software SAS®9.0 and PROC MIXED. The orthogonal contrasts post-test aided the comparisons. The comparisons for orthogonal contrasts do not include adjustments for multiple testing. To study the variation between the groups of variables measured along time, the trapezium rule was employed to estimate the area under the curve (AUC_total and AUC_incremental) for each participant. To compare the variables of quantitative characterization (anthropometric and body composition data, ad libitum energy intake and biochemical and appetite variables in fasting) between the groups, non-parametric Mann-Whitney test was applied for independent samples. The correlations were determined by Spearman correlation coefficient. The level of significance was set at 5% (p < 0.05).

**RESULTS**

**SUBJECT CHARACTERISTICS**

There were no significant differences between the groups HTG and LTG for any anthropometric variables or fasting levels of biochemical parameters and appetite scores (Table I).

**TRIGLYCERIDES (TG) AND POSTPRANDIAL INCRETIN RESPONSES (GIP AND GLP-1)**

In HTG group (n = 16), the TG levels significant change from baseline at 60 min (p < 0.01) and remained at this level up to 180min. In contrast, for LTG group (n = 17), TG levels did not increase significantly as compared with basal levels at any of the evaluated times. The ΔTG (%) was higher in the HTG group compared to LTG group (78.8 ± 44.4% vs. 16.7 ± 18.4%, p < 0.01).

In the HTG group, the AUC_incremental was significant lower when compared to LTG group (2423 ± 1979 pmol.L.min⁻¹ vs. 2809 ± 1042 pmol.L.min⁻¹, respectively, p = 0.03) and AUC_total also presented trend to be lower in this group (p = 0.08) (Table II). GIP was also significantly lower in HTG group at 150 min (16.4 ± 6.4 pmol.L⁻¹ x 12.1 ± 7.3 pmol.L⁻¹, p = 0.03) and at 180 min (13.8 ± 4.7 pmol.L⁻¹ vs. 9.2 ± 6.3 pmol.L⁻¹, p < 0.01) (Fig. 1).

Data are expressed as mean and 95% CI. LTG: low TG change group; HTG: high TG change group. *p = 0.08; #p = 0.02.

Because of the presence of some undetectable and negative values in the postprandial period, it was not possible to calculate the AUCincrementalGLP-1.

The AUCincrementalGLP-1 were similar between groups (Table II). There were no between-group differences for the GLP-1 at each time point (Fig. 1).

**HUNGER, SATIETY, AND AD LIBITUM FOOD INTAKE**

Satiety was significantly lower in HTG group at 120 min (46.4 ± 32.3 mm vs. 67.0 ± 25.2 mm in LTG group, p = 0.03) and at 150 min (30.2 ± 24.4 mm vs. 62.3 ± 26.0 mm in LTG group, p < 0.01). This same trend was noted at 180 min (27.6 ± 29.9 mm vs. 44.5 ± 27.6 mm in LTG group, p = 0.08). There were no between-group differences for hunger at each time point (Fig. 2).

The HTG group showed a higher preprandial hunger (at 180 min) compared to hunger in fasting (64.2 ± 29.4 mm vs. 41.7 ± 35.4 mm, respectively, p < 0.01), which did not occur in LTG group (50.8 ± 31.7 mm vs. 39.6 ± 33.0 mm, respectively, p = 0.22) (Fig. 2).

Despite these findings, ad libitum energy intake, palatability, and preference were similar in both groups (Table I). However, it is noteworthy that HTG group presented 20% higher energy intake compared to LTG group, which corresponded to +97 kcal during this meal.
A positive correlation between preprandial TG levels and AUCTG with ad libitum food intake was found in the total sample ($r = 0.40$, $p = 0.03$ and $r = 0.38$, $p = 0.03$, respectively). Also for the total sample, an inverse correlation between preprandial TG levels and satiety (in the same period) was found ($r = -0.37$, $p = 0.04$). Only in LTG group, a positive correlation between GIP and GLP-1 (in fasting) with satiety ($r = 0.47$, $p = 0.05$ and $r = 0.70$, $p = 0.01$, respectively); and an inverse correlation between ad libitum food intake and AUC$_{totalGLP-1}$ ($r = -0.69$, $p = 0.01$) were observed.

**DISCUSSION**

The findings of this study pointed out that women with larger increase in circulating TG levels after a high-fat meal intake exhibited some differences in incretin and appetite profile, that suggests attenuated postprandial GIP and satiety responses. We also found that preprandial TG levels and AUCTG levels correlated positively with ad libitum food intake, which indicates that TG somehow participated in appetite regulation.

Karatayev et al. (2009) (27) confirm the importance of post-prandial TG levels as a predictor of meal size in animals. However, the possibility that TG levels after a high-fat meal are causally related to subsequent hyperphagia still require further elucidation. Evidences suggests that circulating TG act physiologically on brain mechanisms, through orexigenic peptides, to stimulate feeding and, in particular, to mediate high-fat-induced hyperphagia (17,27,28). In fact, a lower secretion of GIP, which is a hormone with possible actions in the food intake regulation, were observed in the HTG group. Moreover, higher TG levels after a meal could be related to limited TG metabolization by the organism, which would stimulate food intake (29). This might point to difficult energy storage in the adipocytes, which could trigger

---

**Figure 1.**
Postprandial GIP and GLP-1 response along time in LTH and HTG groups (*significant difference between the groups).  

**Figure 2.**
Postprandial hunger and satiety response along time in LTG and HTG groups (*significant difference between the groups).
food intake as an attempt to revert the situation, since the human homeostatic system aims to maintain body storage (1,30).

However, despite these differences for the incretin between HTG and LTG groups, there was no impact on ad libitum energy intake. Some studies that aimed to assess GIP function in appetite and food intake using exogenous infusion of different rates (from 0.8 to 5.0 pmol.kg.min⁻¹) and distinct evaluation times did not find that GIP levels affected hunger, satiety, or prospective food intake (9,10). In contrast, Verdich et al. (2001) (5) showed an inverse correlation between the AUC_increment_GIP and ad libitum food intake, and our study also found a positive correlation between GIP and satiety (in fasting) in LTG group. Methodological differences, especially those related to the type of meal (quantity and quality) used to stimulate GIP secretion, and concomitant exogenous GIP infusion, may have been the reason for the diverse results. This is because several factors, such as chewing (31) and meal size and composition (25,32), can affect GIP levels, which are sensitive to abrupt and chronic alterations in the diet, especially those regarding the fat content (33).

Previous studies have demonstrated that exogenous infusion of GLP-1, in supraphysiological rates, reduces hunger and food intake (8-10). It is also known that GLP-1 reduces food intake in a dose-dependent way and the infusion rate was the only independent predictor of this reduction (3). In our work, it was observed that ad libitum food intake correlated negatively with AUC_increment_GLP-1 in at least one group (LTG group). However, most consistent relationship between GLP-1 with hunger and satiety upon physiologically stimulated secretion (secondary to food intake) were not find. Authors who used a methodological design similar to ours; i.e., GLP-1 secretion stimulated by food intake, did not find any GLP-1 effect on appetite or ad libitum food intake in eutropic and men with obesity (5). Other studies that used infusions of exogenous GLP-1 at low rates (to reflect physiological postprandial concentrations) did also not detect any influence of GLP-1 on food intake (2,34). All these results suggest that, in physiological conditions, changes in GLP-1 alone and after a meal do not significantly impact appetite regulation and subsequent energy intake in the short term, especially in individuals with obesity who seem to have an attenuated GLP-1 response during meals (5-7).

This lack of influence of GLP-1 in physiological conditions can be related to its short half-life, as well as GIP, which hinders the action of these hormones in appetite regulation. Both are, after inactivation and require larger GLP-1 receptor stimulus to produce its anorexigenic effects. Besides that, lipotoxicity (which is associated with high-fat diets intake) affects GLP-1 receptors expression and signaling (40,41). Therefore, individuals with obesity, who are chronically exposed to high-fat diets, undergo rapid GLP-1 inactivation and require larger GLP-1 receptor stimulus to produce its anorexigenic effects. The sample size can be considered a limitation in this study since some analysis showed no conclusive results but rather borderline p-values. Due to the pulsatile incretin secretion, the AUC’s analysis also can be a limitation to find more conclusive results. Furthermore, it is important to consider that other variables related to emotional and environmental factors that influence food intake are difficult to control. The simple fact of participating in a survey can interfere with food intake.

In conclusion, our findings showed that women with larger increments in TG levels after a high-fat meal presented differences in satiety scores and lower postprandial secretion of GIP. This indicated an impaired incretin and appetite profile in women with this metabolic profile, however with no impact on ad libitum food intake in short term.
