Summary

Objectives: To assess serum concentrations of 25-hydroxyvitamin D, 25(OH)D, in osteoporotic patients treated for one year with calcifediol.

Methods: We have studied 156 patients with osteoporosis (23 males and 133 females), aged 71.9±9.6 years who had received treatment with calcifediol for at least one year. Ninety-two of them received 0.266 mg of calcifediol every fifteen days and the remaining 64 the same dose once a month. Serum levels of 25(OH)D, intact PTH (iPTH), procollagen type 1 amino-terminal propeptide (PINP) and C-terminal cross-linked telopeptide of type I collagen (CTX) were determined before and one year after starting treatment.

Results: A significant increase in the concentration of 25(OH)D was observed with both treatment regimens (p<0.001). The percentage of patients who reached levels of 25(OH)D higher than 20 and 30 ng/ml was similar with both guidelines, while the percentage of patients exceeding 60 ng/ml was higher with the biweekly dose (p<0.01). The concentration of iPTH decreased significantly after the administration of calcifediol, although on this occasion there were no differences between the two forms of treatment. Both bone remodeling markers, PINP and CTX, decreased similarly in patients treated with antiresorptives (p<0.0001), without these changes being related to the calcifediol regimen.

Conclusions: The monthly administration of 0.266 mg of calcifediol is adequate to achieve effective levels of vitamin D, and it is also safe enough to avoid reaching potentially harmful levels of it, so it would be preferable to the biweekly schedule in the usual clinical practice.

Key words: calcifediol, PTH, osteoporosis, vitamin D, bone remodeling markers.
Introduction
Opinions vary as to what constitutes normal levels of vitamin D in the general population. According to some authors, severe vitamin D deficiency is when serum levels of 25-hydroxyvitamin D (25(OH)D or calcifediol) are below 10 ng/mL, moderate deficiency when they are between 10 and 20 ng/mL, insufficiency between 20 and 30 ng/mL and adequate values if they are above 30 ng/mL. Others, such as the US Institute of Medicine, propose values for the healthy general population above 20 ng/mL. Nor is there an established excessive, potentially harmful level, although there is a tendency to set this at around 50-60 ng/mL.

As for patients with osteoporosis, most clinical practice guidelines indicate that treatment with antiresorptive or anabolic drugs must be accompanied by an adequate supply of vitamin D, in addition to an appropriate amount of calcium. The latter, whenever possible, should be administered through diet, while vitamin D is recommended to be administered as supplements. An aspect also debated is the serum 25(OH)D levels that patients with this disease should reach, although most authors and scientific societies, including Spanish ones, recommend serum concentrations above 30 ng/mL.

To achieve these aims, a daily dose of 800-1,000 IU of vitamin D (in Europe the vitamin D used is vitamin D3 -cholecalciferol-) is advised, although its weekly, biweekly or monthly equivalent can also be administered. The biological potency of vitamin D is established as international units (IU), so that 1 µg of cholecalciferol equals 40 IU. In some countries, as in the case of Spain, 25-hydroxyvitamin D3, a metabolite of vitamin D, also called calcifediol or calcidiol, is also commercially available. It is prepared in dispensing units containing 0.266 mg. The exact equivalence of this dose with vitamin D in terms of metabolic activity (how many IU of vitamin D activity is 1 µg of calcifediol) is not known with total preclinical activity (how many IU of vitamin D activity is 1 µg of calcifediol). To achieve these aims, a daily dose of 0.266 mg of calcifediol (Hydroferol®) every two weeks or monthly for at least one year (mean ± SD: 15±3 months). Exclusion criteria were the suffering of certain processes (malabsorption, renal failure [Glomerular filtration <45 mL/min/1.73 m²], uncontrolled hyperthyroidism, primary hyperparathyroidism, chronic liver diseases, chronic inflammatory diseases) or the follow-up of treatments that they could interfere with bone metabolism (glucocorticoids, anticonvulsants, antihormonal treatments), as well as previous treatment with vitamin D supplements. Those who recognized inadequate therapeutic compliance were also excluded. The diagnosis of osteoporosis was based on the presence of fragility fractures (vertebral or hip) or the existence of a bone densitometry with T≤2.5 values in the lumbar spine, femoral neck or total hip (DXA, Hologic QDR 4500). The majority of patients also received treatment with antiresorptives (63% with oral bisphosphonates, 9% with zoledronate and 28% with denosumab). Clinical and analytical data were collected through the electronic medical record. In all cases, the month in which the two analytical determinations were made (baseline and after treatment) was collected. The body mass index (BMI) was obtained by dividing the weight in kg. between the height in meters squared. Weight and height were measured while the patient was in underwear and without shoes.

The study was approved by our clinical research ethics committee (CEIC) (2017.023). The criterion for deciding the therapeutic regimen, biweekly or monthly, was based on the baseline of 25(OH)D, preferring the first in cases in which this figure was lower. However, a precise cutting value was not established, leaving the decision to the opinion of the doctor responsible for the patient. The retrospective analysis showed that 90% of the patients who received the biweekly regimen had baseline values lower than 20 ng/mL, while this percentage was only 53% in the case of the monthly regimen.

Material and methods
Patients
We retrospectively reviewed the data of the last 200 osteoporotic patients who had been treated until the time of study in the Bone and Mineral Metabolism Unit of our Center and who had received treatment with 0.266 mg of calcifediol (Hydroferol®) every two weeks or monthly for at least one year (mean ± SD: 15±3 months). Exclusion criteria were the suffering of certain processes (malabsorption, renal failure [Glomerular filtration <45 mL/min/1.73 m²], uncontrolled hyperthyroidism, primary hyperparathyroidism, chronic liver diseases, chronic inflammatory diseases) or the follow-up of treatments that they could interfere with bone metabolism (glucocorticoids, anticonvulsants, antihormonal treatments), as well as previous treatment with vitamin D supplements. Those who recognized inadequate therapeutic compliance were also excluded. The diagnosis of osteoporosis was based on the presence of fragility fractures (vertebral or hip) or the existence of a bone densitometry with T<2.5 values in the lumbar spine, femoral neck or total hip (DXA, Hologic QDR 4500). The majority of patients also received treatment with antiresorptives (63% with oral bisphosphonates, 9% with zoledronate and 28% with denosumab). Clinical and analytical data were collected through the electronic medical record. In all cases, the month in which the two analytical determinations were made (baseline and after treatment) was collected. The body mass index (BMI) was obtained by dividing the weight in kg. between the height in meters squared. Weight and height were measured while the patient was in underwear and without shoes.
Analytical determinations
Serum levels of 25(OH)D, iPTH, PINP and CTX were determined before (baseline) and at least one year (12-25 months) after starting treatment with calcifediol (mean ± SD: 15±3 months).

All determinations were made on an empty stomach early in the morning. The routine determinations (glucose, creatinine, calcium, albumin, phosphate, alkaline phosphatase) were carried out by automated methods in a TechniconDax autoanalyzer (Technicon Instruments, Colorado, USA). The serum concentrations of 25(OH)D, iPTH and markers of remodeling (PINP and CTX) were carried out by an automated chemiluminescence system. In the case of 25(OH)D, the chemiluminescence assay of DiaSorin Liaison (DiaSorin, Stillwater, Minnesota, USA) was used, and in the remaining tests the IDS-ISYS assay (Immunodiagnostic Systems Hokding PLC, London, RU) was used. The limit of detection of 25(OH)D was 4 ng/mL and the intra- and inter-assay variation coefficients (CV) of 4.4% and 8.3%, respectively. Regarding iPTH, the limit of detection was 6 pg/mL, with a normal range of 10 to 45 pg/mL. The intra-assay and inter-assay CVs were 3.7% and 5.4%, respectively. The detection limit of the PINP was 5 ng/mL (reference range between 18 and 102 ng/mL) and its intra-assay and inter-assay CV of 4.6% and 9.2%, respectively. Finally, CTX intra-assay and inter-assay CVs were 5.9% and 10% respectively, and their reference range was 0.152-0.761 ng/mL.

Statistical study
The quantitative variables were expressed as mean ± SD or median (interquartile range) and were compared using Student's t test or Mann-Whitney U test, according to the distribution of the data. The qualitative variables were expressed as number and percentage, and for comparison the χ² test or Fisher's test was used, as appropriate. The differences between the basal and annual values of calcitrope hormones and markers of remodeling were analyzed using the Wilcoxon test. The association between the percentage of change (baseline-annual) of serum levels of 25(OH)D, iPTH, PINP and CTX, and age, sex, BMI, weight and month of the year was determined. The determination of the laboratory was analyzed using the Pearson/Spearman correlation coefficient. Data analysis was carried out using the SPSS v20 statistical package (Chicago, IL). A p<0.05 was considered significant in all calculations.

Results
After applying the exclusion criteria, we finally studied 156 patients (23 men and 133 women) between the ages of 49 and 93 years (mean ± SD: 71.9±9.6). All had received treatment with calcifediol for at least one year, with an average of 15±3 months. Ninety-two of them had received 0.266 mg of calcifediol every fortnight and the remainder 64 received the same dose once a month (Table 1). The patients who received the biweekly regimen were older (4.6 years older, p<0.05). There were, however, no differences in weight or BMI.

As can be seen in table 2, and in accordance with the criterion that had led to the choice of one or another therapeutic regimen, the baseline levels of 25(OH)D were lower in patients who received fortnightly calcifediol than in those who received the monthly dose (p<0.01). In absolute terms, the difference was approximately 7 ng/mL (16.7 ng/mL vs. 23.3 ng/mL). With both treatment regimens, a significant increase in the concentration of 25(OH)D was observed (p<0.001), although these values were higher with the biweekly regimen than with the monthly regimen (in absolute terms, 39.5 ng/mL and 15.5 ng/mL, which meant in relative terms increases of 323% and 85% [p<0.0001]). The final concentration was clearly higher in patients receiving the biweekly regimen (56.2±18.5 ng/mL vs. 38.8±12.5 ng/mL, p<0.01).

The percentage of patients who reached 25(OH)D levels above 20 and 30 ng/mL was slightly higher with the biweekly treatment (100% and 92%, respectively) than with the monthly regimen (97% and 80%, respectively). However, the percentage of patients exceeding 60 ng/mL was higher in patients who received the biweekly regimen of calcifediol, 38%, compared to 6% in patients with the monthly regimen (p<0.01).

The concentration of iPTH decreased significantly after the administration of calcifediol with both treatment regimens. It is interesting to note that, despite the existence of differences in the values of 25(OH)D at the end of the study, the PTH values at that time were similar with the two treatment regimens (Table 2, Figure 1). The changes in the levels of iPTH in absolute terms (-19% vs. -20%) were also similar. Therefore, a clear discrepancy is observed in the behavior of 25(OH)D and PTH.

All patients had normal calcium values at baseline and no case of hypercalcemia was detected with both treatment regimens.

The results of the remodeling markers (PINP and CTX) are also shown in Table 2. As expected, both markers, PINP and CTX decreased significantly in patients treated with antiresorptives (p<0.0001), without these changes will be related to the dosage regimen of calcifediol (biweekly or monthly).

Finally, the changes in the levels of 25(OH)D, iPTH, PINP and CTX had no relationship with age, sex, weight, BMI or the month of the year in which the samples were obtained.

Discussion
In most of the clinical practice guidelines of osteoporosis, recommended serum levels of 25(OH)D are above 20 ng/mL, and even exceed 30 ng/mL. In our study, the vast majority of patients who received monthly or biweekly doses of calcifediol for at least one year exceeded these figures. Specifically, the percentage of patients who reached levels 25(OH)D higher than 20 and 30 ng/mL was 100% and 92% with the biweekly regimen and 97% and 80% with the monthly, respectively.

As expected, the average concentrations of 25(OH)D reached by patients treated with calcife-
diol for at least one year were lower on the monthly than on the biweekly schedule. However, it can be concluded that both guidelines are effective for attaining metabolically sufficient 25(OH)D concentrations. A criterion conventionally used to assess the efficacy of serum levels of 25(OH)D involves its relationship with serum PTH, a negative relationship, since it inhibits the production of serum PTH. Since PTH is thought to be harmful to bone, its inhibition by vitamin D should be beneficial. Although there is no general agreement regarding the exact characteristics of this relationship, the most accepted idea is that as the levels of 25(OH)D rise, PTH decreases until it reaches a value above which the hormone is not suppressed more.

According to what we have been commenting, above this value of 25(OH)D, the beneficial effect does not continue to increase, as the PTH decreases. Although it is not known exactly at which concentration of 25(OH)D this value corresponds, it seems that there is agreement that it should be between 20 and 30 ng/mL, or close to these figures. Our group studied more than 1,800 people (1,154 postmenopausal women and 657 men 50 years and older) and found that the threshold of 25(OH)D needed to prevent the increase of PTH (and the loss of bone mass) would be around 30 ng/mL. The results of the present work point to an equivalent idea when showing that the concentration of iPTH decreases significantly after administering calcifediol without evident differences in the behavior of the hormone between the two treatment regimens. In fact, the reduction obtained with the biweekly schedule was 19% and 20% with the monthly pattern. So, from a certain value, vitamin D no longer exerts beneficial effects.

Studies concerning vitamin D doses and desirable 25(OH)D serum levels have usually focused on aspects related to their efficacy. The possible toxicity of vitamin D has traditionally been related to the development of hypercalcemia, which only occurs with high doses of vitamin D (several thousand-day units) and levels of 25(OH)D in ranges greater than 100 ng/mL. It was thus considered a safe substance. However, over the last few years, data have been appearing suggesting that vitamin D could develop other pernicious effects, independent of hypercalcemia, with much lower levels. So, the idea that, in general terms, the relationship between the beneficial or harmful effects of vitamin D and its levels have a U-shaped relationship (that is, detrimental effects develop both with low levels and with high levels of the vitamin), with the particularity that in the latter case they would begin to settle down with levels of 25(OH)D very inferior to the 100 ng/mL previously commented, having indicated figures of around 50-60 ng/mL. Michaelson et al. observed, for example, followed a cohort of 1,194 males observing a U-ratio between serum levels of 25(OH)D and total mortality. The morphology of the curve was also met in cancer mortality specifically. Durup et al. also described in 247,574 people a reverse association in the form of J between serum levels of 25(OH)D and mortality. Smith et al., in a study conducted with various doses of vitamin D supplements, observed that the effect of the same in

the reductions also shows a U curve, both the relationship in terms of dose and levels of 25(OH)D analyzed. The various research studies carried out in this line do not coincide exactly with the values that could be preferable, but in general terms, reviews and consensus documents indicate that values greater than 50-60 ng/mL should be avoided.5,7

The results of our study show that while the figures reached with the monthly guideline are located in a safety zone (38.8±12.5 ng/mL), those obtained with the biweekly schedule do so in potentially harmful values (56.2±18.5 ng/mL), since the percentage of patients who exceeded 60 ng/mL among those who received the biweekly regimen was 38%, compared to 6% of those who received the monthly (p<0.01). Consequently, our work suggests that the therapeutic regimen with 0.266 mg of calcifediol monthly is the most appropriate. This does not mean, at all, that such a guideline should be considered rigidly, since in the achievement of one or other levels of 25(OH)D, factors of an individual nature are involved (for example, genetic) as circumstantial, which may advise modifying the recommended dose in a specific patient. Hence, the periodic measurement of serum 25(OH)D is recommended to check whether the regimen is adequate.

Regarding the behavior of remodeling markers, as expected, both markers, PINP and CTX, decreased significantly in patients treated with antiresorptives, both in those who received bisphosphonates and in those who received denosumab, without these changes being related to the dosage schedule of calcifediol (biweekly or monthly). This should not be interpreted in the sense that the provision of vitamin D does not influence the response to antiresorptive drugs. In a study carried out by our group in osteoporotic women receiving treatment with alendronate7, some of which were supplemented with 0.266 mg of calcifediol weekly for three months and others not, we found that the response was higher in the supplemented patients, especially when they started from a situation of basal hypovitaminosis (25(OH)D <20 ng/mL).

Among the limitations of our study, it should be noted that this is a retrospective observational study, so we cannot rule out the existence of certain biases (selection, allocation, etc.), as well as confounding factors. For example, in our study, the assignment of patients to one or another treatment regimen was not carried out randomly, but rather in accordance with the criteria of the physician in charge of the patient's care. It is not surprising, therefore, that patients who received the biweekly regimen were older and had baseline values lower than 25(OH)D than those who received the monthly regimen. However, one of the strengths of our study is that it has been carried out under conditions of normal clinical practice.

In conclusion, our results indicate that in patients with osteoporosis being treated for it, the monthly administration of 0.266 mg of calcifediol is, firstly, adequate to achieve effective levels of vitamin D, and secondly, sufficiently safe for avoid reaching potentially harmful levels of it, so it would be preferable to the biweekly schedule in routine clinical practice.
