Fibronectin glomerulopathy in a 88 year-old male with acute kidney injury on chronic kidney disease: A case report and a review of the literature

Glomerulopatía fibronectina en un anciano de 88 años de edad con lesión renal aguda en enfermedad renal crónica: reporte de un caso y revisión sistemática de la literatura

Dear Editor,

Fibronectin glomerulopathy (FGP) was first recognized through direct staining in 1992 by Mazzucco et al.¹ It was regarded as a rare autosomal dominant disease that tends to happen in various age groups and affects both sexes. The clinical features of this disease were proteinuria, typically nephrotic range, microscopic hematuria, hypertension and a slow decline in renal function.^{1–11} However, some patients progress to end-stage renal disease (ESRD) and dialysis has been reported.^{5,12–14} Herein we reported a case of FGP that was diagnosed based on the classic ultrastructural features described above. This case was unique in that FGP presents in a male who was 88 years of age and has no known family history of FGP.

An 88-year-old gentleman was admitted with anuria requiring dialysis for uremic encephalopathy and volume overload. He had an extensive past medical history including chronic renal failure (baseline Cr 200–240 $\mu\text{mol/L}$) one month ago, hypertension, obstructive sleep apnea, mild cognitive impairment, query previous congestive heart failure, diastolic dysfunction, COPD, macular degeneration, benign prostatic hypertrophy and an anemia that was being investigated as an outpatient. Baseline level of proteinuria was unknown. There was no family history of kidney disease.

Relevant initial blood work included a serum creatinine of 1148 $\mu\text{mol/L}$, urea 82.2 mmol/L and potassium 5.7 mmol/L. During his stay in hospital, a 24-h urine collection was done and only 100 mL of urine were collected with 100 mg of protein and a protein excretion of 1 g/L. The other results of blood examination are as follows: a normal ESR, C3 and C4 values, negative ANA, c-ANCA, p-ANCA, anti-GBM antibody, hepatitis B and C serology, renal ultrasound showed normal size

of the kidney. The extranuclear antigen screen was negative except RNP. Immunofixation revealed a serum IgG M-protein with kappa light chain specificity. Bone marrow studies were unremarkable.

A renal biopsy was performed and light microscopy showed a lobular appearance with cellular mesangial nodules that were expanded by matrix. There was also prominent arteriolar fibrointimal hyperplasia and arteriolar hyalinosis. Congo red staining was negative for amyloid. Immunostaining was 2+ for C3 in a granular pattern in the glomerular capillary walls, however staining was negative for IgA, IgG, IgM, kappa, lambda, albumin, fibrin and C1. Electron microscopy showed prominent expansion of the mesangial and subendothelial regions with numerous randomly arranged fibrils seen under high power lens, measuring 10.7–16.8 nm in diameter. Polyclonal rabbit antibody (DAKO, A0245) was used in staining of fibronectin and there was positivity in the mesangium, mesangial nodules and capillary walls (Fig. 1).

The patient received regular hemodialysis and other supportive treatment including anti-hypertension, improving anemia, and preventing renal osteopathy. Unfortunately, this patient died of heart attack half a year later.

To our knowledge, most cases of FGP have presented and been diagnosed in patients under 65-year-old. As this patient was diagnosed with FGP at the age of 88, we reviewed the cases reported in literatures and attempted to explain how this patient's disease course fits within our understanding of FGP.

A PubMed search using the terms “fibronectin glomerulopathy” yielded 16 articles reports in English of patients with biopsy and fibronectin staining proven FGP. This allowed us to compare the disease features of 64 patients, including the patient described in this paper (Table 1). These patients

Table 1 – Reported cases of fibronectin glomerulopathy.

Figure 1

received renal biopsy at the age of 3–88, which was a wide range. The majority of patients had proteinuria for more than 5 years before being diagnosed, which supported the idea that the onset of disease occurs at younger ages. Most of the reported cases were patients in European countries, and there were several cases reported in Asia in recent years.

FGP is understood to present with nephrotic range proteinuria and we found 23 (35.9%) of the 64 cases that reported proteinuria were nephrotic range. 21(32.8%) patients had microhematuria at the time of biopsy. Slightly more than half of the cases had hypertension. There was no association between degree of proteinuria, microhematuria and hypertension. The degrees of renal impairment at the time of biopsy were variable. Most of them had slow decline in renal function. 22 (34.3%) patients' serum creatinine was stable, and 24 (37.5%) patients progressed to ESRD or dead. What appears different was that our patient had severe renal impairment at the time of his diagnosis.

In general, the timing of disease seems to be the distinguishing feature of our patient. Our patient had a history of chronic kidney disease on the basis of hypertension, however he came to hospital with ESRD requiring dialysis and a renal biopsy led to the discovery of FGP. With the usual disease course of FGP being slowly progressive with proteinuria of several years' duration, it is possible that our patient had FGP and hypertensive kidney disease for many years and that a third insult may have precipitated ESRD. In his case it may have been the concomitant pneumonia.

In conclusion, FGP is an autosomal dominant disease that has an indolent disease course after a typical presentation in adulthood. Here we reported a case of FGP diagnosed in an 88-year-old gentleman at the time of his progression to ESRD. This may suggest that he had an exceptionally long indolent course if the onset of disease was during middle age, or

perhaps he had an atypically late onset of disease. Further studies are needed to characterize the disease course in FGP as well as the tendency of FGP to ESRD.

Yours sincerely,

Aneurisma humeral verdadero en relación con acceso vascular en paciente trasplantado renal: a propósito de 2 casos clínicos

True brachial artery aneurism following vascular access for haemodialysis in renal transplant patient. Two case reports

Sr. Director:

Los aneurismas de la arteria humeral (AAH) son una entidad poco frecuente, generalmente secundarios a traumatismos, infecciones o a enfermedades del tejido conjuntivo^{1,2}. También se han descrito en el contexto de fistulas arteriovenosas (FAV) para hemodiálisis; la mayoría son pseudoaneurismas anastomóticos o de origen venoso, siendo escasos los aneurismas arteriales degenerativos verdaderos. Presentamos 2 casos de AAH verdaderos:

Caso 1

Varón de 44 años que inició hemodiálisis a los 20 años (1978) a través de una FAV radiocefálica izquierda por una glomerulonefritis rápidamente progresiva. Durante el transcurso de su enfermedad recibió 2 trasplantes renales. En 1996 se realizó una nueva FAV radiocefálica en la extremidad contralateral por trombosis de la previa. En el 2003 se detectó un AAH verdadero asintomático de 6 cm de diámetro, confirmado

mediante arteriografía. Se practicó resección aneurismática e interposición de la vena safena interna invertida extraída del miembro inferior izquierdo. Dos años más tarde se detectó una dilatación aneurismática de 4,5 cm del injerto venoso (fig. 1A), reparado mediante interposición de prótesis de PTFE. Durante el seguimiento no se detectaron otras complicaciones, siendo exitus en el 2009 por un carcinoma renal metastásico de células claras.

Caso 2

Varón de 55 años, exfumador y con hipertensión arterial mal controlada, que inició hemodiálisis a los 40 años (2000) a través de una FAV radiocefálica izquierda por una nefroangiosclerosis maligna, recibiendo un trasplante renal en 2001. Como otros antecedentes, destacaba un aneurisma poplíteo en miembro inferior derecho, intervenido mediante *bypass* fémoro-poplíteo de vena safena invertida, que precisó amputación supracondílea por trombosis aguda del mismo. En 2007 se cerró la FAV por degeneración aneurismática venosa. En 2015 se diagnosticó un AAH verdadero asintomático de
