Summary
The immune system and the bone often share the same anatomical niches and spaces, as there is a close functional relationship between both of them. As a consequence, there is a constant interaction between them and a bidirectional flow of information between the immune cells and those of the bone tissue (osteoclasts, osteoblasts, and osteocytes) often unknown, in which multiple inflammatory mediators and various growth and cell differentiation factors are involved. This leads to a very close interaction between inflammation and bone loss. In fact, osteoporosis (OP) is one of the most frequent systemic complications in chronic inflammatory diseases (CIDs). The prevalence of OP in CIDs depends on each pathological scenario. Rheumatoid arthritis (RA) is a paradigmatic disease which causes chronic inflammation, where the presence of OP is frequent and shows even prior to the appearance of the first symptoms of the RA. The pathogenesis of RA-associated OP is complex and includes the cooperation of multiple pro-inflammatory cytokines that promote osteoclastogenesis and inhibit bone formation. Tumor necrosis factor alpha (TNF-α) and different interleukins (IL), such as IL-1, IL-6, and IL-17, stand out among all, IL-6 having a relevant hierarchical role. In this study, we review the role of pro-inflammatory cytokines in bone and joint destruction in different CIDs, giving special emphasis to RA, as we set out the bases of possible pathways that open new therapeutic horizons in their framework.

Key words: osteoporosis, rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, pathophysiology, interleukins, IL-6, treatment.

CHRONIC INFLAMMATORY DISEASES
Chronic inflammation is a nonspecific response against aggressor agents mediated by the body’s immune system. In such a scenario, an infiltrate of predominantly mononuclear cells, such as lymphocytes, macrophages, and plasma cells, is produced. Under certain conditions or when the aggressor agent persists, a sustainable accumulation and activation of immune cells occurs. Then, the secretion of cytokines, agents that prolong the life of lymphocytes and macrophages, is increased, what leads to chronic inflammation.

Inflammation is the main mechanism involved in bone destruction in chronic inflammatory diseases (CIDs)1, such as rheumatoid arthritis (RA), ankylosing spondylitis (AS), psoriatic arthritis (PsA), systemic lupus erythematosus (SLE), multiple sclerosis and/or inflammatory bowel disease (IBD). These diseases show a chronic systemic inflammation that can affect different organs, caused by an alteration of the immune system2.

One of the characteristics of CIDs is the common symptoms that patients present: malaise, fatigue, daytime sleepiness, weakness, nonspecific arthromyalgia, hyporexia, anxiety, and low mood1. Inflammatory joint diseases encompass more than 100 different and heterogeneous disorders that affect the joints and cause disability. However, RA and spondyloarthritides (SpA: AS, reactive arthritis, PsA and SpA associated with IBD) are the most frequent1. RA is an autoimmune disease considered the prototype of destructive inflammatory arthritis and characterized by chronic inflammation of the synovium in multiple joints and tendon sheaths. The synovial membrane is the target organ where the immune system interferes with bone homeostasis, producing severe structural damage and bone destruction there where joint and peri-articular inflammation exist3,4. In fact, in patients with inflammatory rheumatic diseases, bone destruction occurs together with erosions, periaricular osteopenia and/or generalized osteoporosis (OP)4,5.
The cause of RA-associated OP has its origin in an alteration of bone remodeling, which is the common pathophysiological mechanism of both diseases. The loss of bone mass in RA can be periarticular or generalized. Periarticular loss, commonly called juxta-articular OP, affects the trabecular and cortical bone and is one of the first radiological manifestations. It can precede both the appearance of erosions and damage to the joint space, and is easily detected on X-rays of the hands. Accelerated bone loss in the hands has been associated with the development of RA in patients suffering undifferentiated arthritis and presenting progressive joint disease in the hands and feet at the onset of RA.

Another form of RA bone loss involves erosion of the marginal bone as a consequence of inflammation of the synovial membrane. The erosion, generally irreversible, may begin before arthritis symptoms appear and is related to the severity of the disease and functional impairment. Finally, and due to autoimmune mechanisms, RA usually produces generalized bone loss (systemic OP), inclusively in those regions of the skeleton located far from the inflamed joints even in the initial stages of the disease.

**The Bone System and the Immune System**

The musculoskeletal system and the immune system closely interact in the homeostasis of hemopoietic and lymphopoietic cells, acting in the pathogenesis of CIDs-associated OP as well as in postmenopausal OP but it remains to be explained how adaptive immune responses affect the bone tissue. However, recent evidence has revealed that the reverse is also true: bone cells regulate immune cells, a concept consistent with the established role of bone marrow in the development and homeostasis of the immune system.

Due to its anatomical characteristics, both the in and out of the bone tissue are closely related to the immune system. In the inside, in the bone marrow, hematopoiesis occurs, so bone and immune cells locally work together in an indisputable way. At the outside, the skeleton is in direct contact with the periosteum, enthesis, and juxta-articular bone, where it connects with determining structures that have a role in the joint destruction process that characterizes chronic inflammatory joint diseases (CIDs).

Likewise, the immune system and bone tissue are connected to the general circulation by nutritional and periosteal vessels that cross the cortical bone, and, within the bone compartment, this connection is produced through fibrous enthesis junctions and calcified components of cartilage and fibrocartilage.

This permanent interaction between bone and immune system is of great importance in maintaining bone homeostasis and is also key in bone pathology. Throughout adult life, bone remodeling occurs in basic multicellular units (BMUs) or bone remodeling units, where osteoclasts reabsorb a certain amount of bone, and osteoblasts form the osteoid matrix and mineralize it to fill the previously created cavity (Figure 1). There are osteoclasts, macrophages, preosteoblasts and osteoblasts inside BMUs that are governed by a series of factors, both general and local, and allow the normal functioning of bone tissue and the maintenance of bone mass.

Bone cells interact with the immune system cells in the bone marrow development during growth and the healing of fractures. Apart from that, osteoblasts play an important role in controlling the renewal and differentiation of hemopoietic stem cells and B cells in places close to the endosteum.

A series of substances synthesized by bone cells, immune system cells or bone marrow have an effect on bone growth and remodeling. The most important local factors are growth factors, cytokines, and bone matrix proteins (Table 1).

The musculoskeletal and the immune systems interact with each other; sharing molecules and generating a collaborative regulatory system called "osteoimmune system". The most representative and well-known molecule of this system is the receptor activator of nuclear factor kappa B ligand (RANKL), which fulfills multiple functions, both under physiological conditions and in conditions as different as RA and bone metastases. Based on current evidence showing great mutual dependence, it is accepted that the relationship between bone and the immune system does not develop by accident, but as a necessary consequence of evolution.

RANKL expression in osteoblasts is stimulated by various factors or molecular mediators, such as the interleukin (IL) 1, IL-6, IL-11, IL-15, IL-17, TNF-α, prostaglandin E2, parathormone (PTH), calcitriol, interferon and glucocorticoids (GCs), and is suppressed by the transforming growth factor-β (TGF-β) (Table 1). On another note, the

osteoprotegerin (OPG) expression is stimulated by the TGF-β, bone morphogenetic proteins (BMPs), interferon (IFN), IL-6, IL-11 and IL-13 and is inhibited by the PTH, IL-17, calcitriol and GCs. Estrogens inhibit RANKL production and increase OPG and TGF-β secretion (Table 1)\(^5\)\(^{13}\)\(^{15}\)\(^{16}\).

The immune and bone systems share, indeed, a wide range of regulatory mechanisms, and today we can assert this influence to be bidirectional, not only of the immune system on the bone, but also in the opposite direction\(^6\)\(^{12}\). In fact, in the bone marrow microenvironment, bone cells and immune system cells are so closely located that their interaction is logical\(^7\).

The RANK/RANKL/OPG system is the promoter of most of the factors that regulate bone resorption. It belongs to the group of proteins related to tumor necrosis factor α (TNF-α) and actively participates in the control of bone resorption and activation of osteoclasts\(^15\). Although the RANK/RANKL/OPG pathway remains the basis for understanding the coupling of the immune system cells with those of the bone system, some research suggests that there may be additional stimuli and unique pathways that act independently or in concert with RANK\(^2\).

Systemic inflammation in RA increases the production of inflammatory cytokines, such as TNF-α, IL-1, IL-6 and IL-17, which act on the RANK/RANKL/OPG system, activating osteoclastogenesis and increasing bone resorption, due to RANKL’s wide expression in synovial fibroblasts and in the T cells of inflamed joints of RA patients\(^17\). This abnormal activation of osteoclasts in the absence of equivalent levels of osteoblastic activity results in a generalized decrease in bone mass and a higher incidence of vertebral and non-vertebral fractures\(^8\)\(^9\).

The immune regulation of osteoclasts is closely related to the RA pathogenesis. There is evidence that RA bone destruction is primarily caused by the increased in osteoclast activity as a result of the activation of a unique subset of T helper cells, the T helper 17 cells (Th-17). These cells have a low production of IFN gamma (IFN-γ) and are capable of causing local inflammation through the production of pro-inflammatory cytokines\(^2\).

Mature Th-17 cells produce IL-17, IL-21, and IL-22, all of them cytokines with high pro-inflammatory activity. In RA, IL-17 produced by Th-17 cells exerts its osteoclastogenic effect by stimulating RANKL expression in synovial fibroblasts\(^8\)\(^9\). In immune precursor cells such as macrophages, IL-17 also stimulates the production of inflammatory cytokines, including TNF-α, IL-1β and IL-6, and get in contact with the RANK of osteoclast precursors, all this leading to the differentiation of osteoclasts, provoking them to migrate towards the marginal zone where erosions begin\(^10\)\(^{11}\). Furthermore, synovial cells stimulated by inflammatory cytokines also produce matrix-degrading enzymes that play an important role in articular cartilage destruction\(^11\).

**ROLE OF INTERLEUKIN-6 (IL-6) IN RA AND OSTEOPOROSIS**

IL-6 plays an essential role in the pathophysiology of RA and associated bone destruction. Through cell signalling, which can be initiated in the cell membrane or by soluble forms of its receptor, IL-6 acts both locally, promoting joint inflammation and destruction, and systemically, causing some of the extra-articular and systemic manifestations of the disease, including pain, fatigue, morning stiffness, anemia, depression, low mood and weight loss\(^13\)\(^{15}\)\(^{21}\).

IL-6 actions are mediated through the interaction between its non-signalling receptor-α, the IL-6 receptor (IL-6R), with which it interacts first, and subsequently forms a bond with the transduction receptor of signals, the glycoprotein (gp) 130\(^2\). IL-6Rα is expressed in hepatocytes, monocytes/macrophages, neutrophils, and some types of T cells\(^15\).

Through intracellular signalling by binding to its membrane receptor or by the classical pathway, IL-6 regulates normal processes related to the immune and neuroendocrine systems, hematopoiesis, bone metabolism, lipid and glucose metabolism and acute phase responses. When IL-6 binds to its soluble IL-6R receptor, it predominantly regulates systemic pro-inflammatory effects, including monocyte recruitment, macrophage differentiation, and T cell recruitment and differentiation. Its bond with cell
membrane’s gp130 prolongs its life average, which is why elevated IL-6 values are observed in the serum and synovial fluid of these patients. Apart from this, IL-6 is an effective stimulator of osteoclast-induced bone resorption and is essential for the pathogenesis of bone loss in the context of chronic inflammation, as occurs in other pathologies such as IBD. Elevated IL-6 values in patients with RA produce an increase in osteoclastogenesis and an imbalance of bone remodeling in favor of resorption, which leads to a generalized bone mass loss and, secondarily, osteoporosis.

In the preclinical state of RA, IL-6 binds to various cell lines and causes neutrophil migration to the joints, contributing to the development of chronic inflammation, impaired B and T cell differentiation, and angiogenesis. Subsequently, osteoclasts are stimulated to produce acute phase reactants such as C-reactive protein, fibrinogen, and serum amyloid A. IL-6 in serum is related to the disease itself, inflammatory activity or treatment, resulting in an increase in physical disability. As mentioned previously, one of the deleterious effects induced by RA chronic inflammation is the bone mass loss produced by the imbalance in bone remodeling in favor of resorption. Likewise, the use of GCs in RA patients for more than three months increases the bone mass loss, especially trabecular mass loss, raising vertebral and hip fracture risk. A more recent study concluded that the incidence of fractures in patients receiving GC treatment is even higher than is known, especially at the beginning of the treatment. Thus, an annual incidence of vertebral fracture of 5.2% was detected in patients with RA and GC treatment is the treatment of choice when bone-forming treatment is to be started.

To our knowledge, no randomized controlled trials with bisphosphonates have been published regarding patients with RA-association OP with fracture as primary endpoint, but only regarding patients with GC-induced RA and OP. In these patients, bisphosphonates prevent bone loss in the lumbar spine and femoral neck and reduce the risk of vertebral fracture after 24 months of treatment, but have no effect on the prevention of non-vertebral fractures. Although bisphosphonates are the first-line treatment for OP, denosumab has demonstrated its antiresorptive efficacy in patients with primary and secondary OP. Denosumab is a human monoclonal antibody (IgG2) that targets and binds with high affinity and specificity to RANKL, preventing the activation of its receptor, RANK, on the surface of osteoclasts and their precursors. By preventing the RANKL/RANK interaction, osteoclast formation, function, and survival are inhibited, which in turn causes decreased bone resorption in trabecular and cortical bone. In a randomized and controlled trial, treatment with denosumab and calcium and vitamin D supplements significantly increased lumbar spine and total hip BMD after 6 and 12 months, reducing the risk of fracture and also reducing the radiological progression of arthritis in RA patients treated with methotrexate.

Teriparatide acts as an anabolic drug by increasing bone formation, stimulating osteoblastogenesis and decreasing the osteoblasts and osteocytes apoptosis. In clinical practice, it has been observed that teriparatide treatment reflects a significant increase in BMD and a decrease in vertebral fractures in RA patients under GCs treatment. These results were endorsed by the same authors in an integrated analysis consisting of four observational studies under clinical practice conditions, in which a reduction of non-vertebral fractures was also observed. However, these results should be viewed with caution, since they are uncontrolled studies.

**Effect of IL-6 inhibitory therapies on bone loss during RA**

As mentioned previously, one of the deleterious effects induced by RA chronic inflammation is the bone mass loss produced by the imbalance in bone remodeling in favor of resorption. Likewise, the use of GCs in RA patients for more than three months increases the bone mass loss, especially trabecular mass loss, raising vertebral and hip fracture risk. A more recent study concluded that the incidence of fractures in patients receiving GC treatment is even higher than is known, especially at the beginning of the treatment. Thus, an annual incidence of vertebral fracture of 5.2% was detected in patients in an early stage of the treatment, this incidence decreased to 3.2% in those under prolonged treatment.

Treatment of RA with IL-6 antagonists is effective in controlling inflammatory activity, since this cytokine not only causes local inflammation, but also damage to bone structures due to its ability to stimulate the expression of the RANKL and osteoclastogenesis. Sarilumab and...
tocilizumab are two biological drugs approved in Spain for the treatment of RA. Their mechanism of action is based on blocking the IL-6 receptor.

The effect of tocilizumab and sarilumab on the biochemical markers of bone remodeling, both formation and resorption, has been analyzed in some clinical trials. In the MONARCH study, monotherapy with sarilumab compared with that with adalimumab, achieved a significantly greater reduction in the RANKL biomarker for bone resorption, and a greater increase in the markers of procollagen type I N-terminal propeptide (P1NP) and osteocalcin. In this and other trials, it has been shown that the decrease in RANKL levels and in RANKL/OPG ratio begins in the early stages of the treatment (week 2 after the start of the treatment with sarilumab), and that the decrease is maintained and even progresses during the 24 weeks of the study.

Tocilizumab treatment over one year has not shown some significant changes in BMD in patients with normal baseline values, but in those with osteopenia. After two years of treatment, tocilizumab has shown a significantly increased BMD in the femoral neck in patients with positive cyclic anti-citrullinated peptide antibodies (ACPA). Regarding bone remodeling biomarkers, tocilizumab significantly increases bone formation, achieving a 25% reduction in the carboxy-terminal telopeptide of type I collagen (CTX-I) osteocalcin ratio after 16 weeks of treatment, a small decrease (<15%) in the CTX-I and cross-linked carboxy-terminal telopeptide of type I collagen resorption biomarkers generated by matrix metalloproteinases (ICFP) at 24 weeks, and a significant increase in osteocalcin levels in 100% of patients at the end of the 52 weeks of treatment.

All these data together suggest that the specific blocking of IL-6 could produce a direct anti-osteoporotic effect which is added to its indirect beneficial effects, such as the clinical control of the disease activity or the reduction, and even withdrawal of the systemic inflammatory activity. Anti-TNF agents have also shown some efficacy in reducing systemic bone loss in RA.

SECONDARY OSTEOPOROSIS CAUSED BY ANKYLOSING SPONDYLITIS AND OTHER CIDs

25% of patients with AS present OP and an increased risk of vertebral and non-vertebral fractures. Although bone loss depends on multiple factors, the effect of pro-inflammatory cytokines (TNF-α, IL-1 and IL-6) on osteoclast activation appears to be one of the main ones. In advanced stages of the disease, the decrease of BMD and the occurrence of fractures are also influenced by mechanical factors due to immobility, and spine stiffness.

The assessment of BMD in AS in the spine using traditional DXAs is more difficult to carry out because of the appearance of ossification/syndesmophytes, especially in late stages of the disease, which can overestimate the assessment of the subject's calcium mineral content, although bone loss has been detected in other anatomical regions such as the hip even in the initial stages of the disease. A decrease in bone mass has been also detected in the spine using other techniques, complementary to DXA, such as DXA assessment using lateral projection, less sensitive to artifacts, or by applying the trabecular bone score (TBS), which allows visualization of the bone micro-texture of the vertebral body avoiding the addition of calcium that supposes the presence of syndesmophytes or other juxta-vertebral ossifications, and which is a good predictor of clinical vertebral fracture and major osteoporotic fracture in patients with AS, regardless of the FRAX®.

The treatment with TNF-α inhibitors, the most widely used biological treatment, in these patients, not only reduces the inflammatory activity of the disease, but also improves the quantification of remodeling biomarkers and increases BMD, although it is not yet clear that they reduce the incidence of new fractures.

The prevalence of OP and fracture risk in patients with psoriasis and PsA is a widely debated issue, still unclear at the present time. Traditionally, there is a higher prevalence of OP in patients with psoriasis and PsA, when compared with the control population. Regarding fractures, in a population-based study carried out by Ogdie et al., patients with psoriasis and PsA were reported to have a higher risk of fractures, with an adjusted hazard ratio (HR) of 1.26 (1.06-1.27) in patients with PsA, while patients with severe or severe psoriasis would have increased risk of any type of OP fracture as well as vertebral fractures: adjusted HR of 1.26 (1.15-1.39) and 2.23 (1.54-3.22), respectively.

However, other authors do not seem to find in patients with PsA a prevalence of OP higher than in the general population, except for those presenting more severe polyarticular involvement and poorer functional grade.

Finally, SLE patients, a prototype of chronic systemic autoimmune disease, also have a higher incidence of OP and fractures than the general population, due to the confluence of several factors such as: prolonged treatment with GCs, use of anticoagulants and immunosuppressants, periods of transient amenorrhea suffered by many patients with SLE in flare-ups, vitamin D deficiency and low physical activity, in addition to the inflammatory activity of the disease caused by various cytokines and pro-inflammatory mediators.

CONCLUSIONS

CIDs frequently present associated OP, although with different prevalence and severity depending on the type of underlying disease. CIDs include RA, AS and PsA. RA is the prototypical disease that appears together with chronic inflammation and OP and, therefore, the only one included in different fracture risk assessment scales such as FRAX®. In fact, RA is a disabling disease, frequently associated with localized and generalized OP, in approximately one third of patients. The incidence of OP in RA patients depends on multiple factors, such as disease severity, age, prolonged use of corticosteroids, sarcopenia, and periods of prolonged immobilization. IL-6 is a crucial pro-inflammatory cytokine that plays a relevant role in the pathogenesis of joint inflammation and RA-associated OP. Treatment with IL-6 neutralizing agents improves both the joint and systemic symptoms, as well as the associated OP.

AS and PsA are also chronic inflammatory diseases that are associated with OP to a lesser extent, at least in its early stages, and which involved molecular mechanisms are less understood. The use of anti-TNF drugs in these patients have increased BMD and improved bone remodeling biomarkers, although their effect on fractures is more doubtful, so longitudinal clinical studies are needed to corroborate these incipient findings.
In all patients with a diagnosis of CIDs, especially RA, BMD and the risk of fractures should be early assessed, in order to start preventive treatment, at least consisting of calcium and vitamin D supplements and/or to administer a basic anti-osteoporotic treatment to try to prevent this dreaded complication, especially in cases with a higher risk of fracture.

Acknowledgments: To patients with chronic diseases, for everything they convey and teach us every day.
