Summary
Treatment for osteoporosis is usually long term, so it is often necessary to implement a sequential treatment strategy. The clinician must know not only how to select the best available therapy in each clinical situation, but also how to discontinue or change treatment at a certain point in the evolution of the disease.

Here, we briefly review the mechanisms of action and the consequences of discontinuing each of the drugs for osteoporosis, as well as what happens with the different treatment sequences.

Discontinuation of denosumab has clearly negative consequences for the skeleton, and only bisphosphonates, due to its particular remaining antiresorptive effect, could be discontinued for a limited time (drug holidays).

Switching from antiresorptive to another antiresorptive with a different mechanism of action is an option that may be favorable in the management of some patients with osteoporosis. Switching from antiresorptive to anabolic may be associated with an initial bone mineral density loss that does not appear to have negative consequences on antifracture efficacy. Starting with anabolic (teriparatide or romosozumab) and subsequently switching to antiresorptive is the best treatment sequence, so it could be the preferred option in patients who present a very high risk of fracture.

Key words: sequential therapy, osteoporosis, treatment, antiresorptive, bone formation.

INTRODUCTION
Osteoporosis is a chronic systemic disease characterized by a deterioration in bone density and/or quality, which predisposes to a greater risk of fracture1.

All treatments for osteoporosis have shown greater or lesser efficacy in reducing the risk of fracture, especially in postmenopausal women2. This beneficial effect occurs from the modification of the bone remodeling process with the consequent increase in bone mineral density (BMD) and/or a modification of the bone’s microarchitecture, although this requires a prolonged treatment over years in most cases.

Although treatment with antiresorptives, menopausal hormone therapy [THM], selective estrogen receptor modulators [SERM], bisphosphonates [BP] and denosumab [DMAB]) can be maintained for at least 5–10 years, the balance between risk and benefit should always be taken into account, since in prolonged treatments with the highest antiresorptive potency drugs (BP and DMAB) an increased risk of some very infrequent complications such as osteonecrosis of the maxilla or atypical femur fracture has been described3,4.

In the case of bone-forming drugs (teriparatide [TPTD] and abaloparatide [ABL]) or dual-effect drugs (romosozumab [ROMO]), the duration of treatment is limited to a shorter period of time. TPTD and ABL (the latter not authorized for marketing in Europe) are not recommended to be administered for more than 2 years5,6, and ROMO should not be administered beyond 12 months7.

In recent years, the term sequential treatment has been gaining importance in the management of patients with osteoporosis, that is, the sequential use of different treatments to achieve maximum efficacy with the least risk of complications8.
ADVANTAGES OF A SEQUENTIAL TREATMENT

In managing patients with osteoporosis, a sequential treatment strategy over the years is often required. After using a treatment for a certain period of time, it can be beneficial to discontinue or replace it with a different one, as a sequence.

There are several reasons that justify sequential therapy in patients with osteoporosis:

1. Osteoporosis is a chronic disease that requires long-term treatment, probably for many years.
2. Some treatments for osteoporosis have a maximum recommended duration (for example, 2 years for TPTD and ABL or 1 year for ROMO).
3. Some treatments are associated with some infrequent complications, especially if they are used for more than a certain time (for example, atypical femur fractures are more frequent in patients treated with BP for more than 5 years).
4. With some of the osteoporosis treatments there is a loss in BMD gain if a different one is not administered after its discontinuation.
5. In some cases, greater efficacy is achieved when a sequence of 2 or more drugs is used than if a single drug is used in the same period of time.
6. Patients tend to get tired and lose adherence to treatments, when they are administered very chronically for years, without changes in the administration guidelines.
7. Sometimes there is an inadequate response to treatment, either due to a loss of BMD or the development of new fractures despite following the treatment correctly; or simply an insufficient response to reach a therapeutic objective (“treat-to-target” strategy).

In all these situations we should propose a change in the treatment for osteoporosis. Although in some cases a temporary interruption might be better, in most situations it would be more appropriate to substitute a different treatment.

It is thus very important that the clinician knows the advantages and disadvantages of the different sequences of treatments in the patient with osteoporosis.

MECHANISM OF ACTION OF DRUGS FOR OSTEOPOROSIS

For the proper management of the patient with osteoporosis, knowing how to select the best available therapy in each clinical situation is crucial, as well as discontinuing or changing when the risk-benefit balance recommends. It is therefore essential to be very familiar with the mechanism of action, effectiveness and safety of each of the drugs.

Menopausal hormone therapy (MHT)

Treatment with estrogens, alone or in combination with progestogens (depending on whether the patient retains her uterus or not), acts through the activation of nuclear estrogen receptors (ERx and ERβ) distributed in different body tissues. ERx receptors predominate in bone, their stimulation on the one hand inhibits osteoclastogenesis from the inhibition of the ligand of the activating receptor for nuclear factor kappa B (RANKL) and the stimulation of osteoprotegerin (OPG)10, and, on the other hand, effects on bone formation have been described, through the stimulation of factors such as IGF-1 or the inhibition of sclerostin11. In bone remodeling, MHT has an antiresorptive effect, with the consequent increase in BMD and a decrease in the risk of vertebral, non-vertebral and hip fracture, especially when administered in the first 5-10 years after the menopause12.

However, given the much debated risk of breast cancer and cardiovascular complications in prolonged estrogen treatments only confirmed in treatments started beyond the age of 60, it is currently assumed that MHT is reserved for women with prematurity ovarian failure and for those under 60 years of age with overt climacteric symptoms, in which the benefits clearly outweigh the risks13.

Selective estrogen receptor modulators (SERMs)

SERMs are a group of drugs with agonist activity at bone estrogen receptors, inhibiting resorption, and antagonist at estrogen receptors in the breast and endometrium, which is why they can provide the beneficial effect of estrogens in patients with osteoporosis, minimizing the effects of adverse effects on other organs14.Raloxifene (RLX) and bazedoxifene are the SERMs indicated in women with postmenopausal osteoporosis, since they increase BMD and reduce the risk of vertebral fracture. The unproven efficacy in reducing the risk of non-vertebral or hip fracture and the increased risk of venous thromboembolism restrict its use to postmenopausal women under 70 years of age at risk of vertebral fracture and low risk of hip fracture and venous thrombosis15.

Bisphosphonates (BP)

BPs are compounds derived from inorganic pyrophosphate with a high affinity for bone hydroxyapatite, which, when taken up by endocytosis by the osteoclast, inhibit farnesyl pyrophosphate synthetase and lead to cell apoptosis, with the consequent inhibitory effect on bone resorption16.

Alendronate (ALN) and risedronate (RIS), taken by mouth, and zoledronic acid (ZOL) by intravenous route, are the BP most widely used and recommended by clinical guidelines, given the demonstrated efficacy both in increasing BMD and in reducing the risk of vertebral, non-vertebral and hip fracture15,17. Ibandronate (IBN) is another oral BP, which, although it offers the advantage of its monthly administration, has only shown a reduction in the risk of vertebral fracture17.

Some infrequent complications associated with prolonged treatment with BP have been described, such as osteonecrosis of the maxilla and atypical fracture of the femur, with incidences of 0.1-1/10,000 and 1-2/10,000 patient-years, respectively15.

Denosumab (DMAB)

DMAB is a completely human monoclonal antibody, administered subcutaneously, with a potent antiresorptive activity, through the blockade of RANKL18. DMAB has been shown to continuously increase BMD, for at least 10 years, and reduce the risk of vertebral, non-vertebral, and hip fractures15,19. DMAB has demonstrated superiority to BP in terms of increases in BMD, and its prolonged treatment has also been associated with osteonecrosis of the maxilla and atypical femur fracture, although also with a very low incidence20.

Teriparatide (TPTD) and abaloparatide (ABL)

TPTD and ABL are synthetic parathormone analogues (PTh 1-34 and PThrP 1-34 respectively) with bone-forming activity and approved for treating osteoporosis with high risk of fracture (the EMA has only approved TPTD). Both drugs bind to the PTH receptor (although with affinity to different conformational states) and inhibit sclerostin, thereby stimulating osteoblastogenesis,
and decreasing apoptosis of osteoblasts. Later, and to a lesser degree, they increase RANKL secretion and therefore bone resorption. Both treatments produce an increase in bone mass and improve the microarchitecture of the skeleton, especially in the trabecular bone, increasing bone strength and reducing the risk of fracture.

Both drugs are indicated in the treatment of patients with osteoporosis at high risk of fracture and have shown superiority over BP, but should not be administered beyond 2 years according to the technical data sheet.

**Romosozumab (ROMO)**
ROMO is a humanized antibody for subcutaneous administration with a dual effect on bone remodeling, as it inhibits sclerostin and secondarily RANKL, producing a rapid, but transitory, increase in bone formation (osteoblasts) associated with a more sustained decrease over time of bone formation. As a consequence, with this treatment there is a marked increase in BMD (greater than with TPTD) and a decrease in the risk of fracture.

Unlike what happens with TPTD or ABL, the increase in bone formation that occurs with ROMO is mainly due to a marked increase in bone shaping (bone formation after activation of the lining cells in quiescent areas, without a process of prior resorption).

The beneficial effects of ROMO are both on the trabecular bone and on the cortical bone. However, in its development, doubts have appeared in relation to cardiovascular safety, which have not yet been resolved. In the ARCH study, comparing with ALN, a higher incidence of serious cardiovascular events was observed in women treated with ROMO.

ROMO has been approved by the EMA, although as of the writing of this article it is not yet marketed in Spain.

According to the technical data sheet, it can only be administered for 12 months and is contraindicated in patients with a history of myocardial infarction or stroke. In addition, the cardiovascular risk of patients should be assessed, based on risk factors, before and during its administration.

**DISCONTINUING OSTEOPOROSIS TREATMENTS**

**THM discontinuation**
Discontinuation of estrogen treatment involves increased remodeling in some patients, with a rapid decrease in BMD and progressive loss of anti-fracture efficacy, which can be prevented with the administration of BP.

**SERM treatment discontinuation**
Discontinuation of treatment with X-ray is accompanied by a loss of BMD in both the lumbar spine and the femur, although less than that produced with estrogen interruption and proportional to the physiological loss that occurs with age.

**Discontinuation of BP treatment**
BPs are the only drugs for the treatment of osteoporosis with a residual effect on the skeleton after its discontinuation, the duration of which will depend on the affinity for hydroxyapatite of each BP, ranging between 1-2 years for RIS and IBN and 2-3 years for ALN and ZOL.

After discontinuation of treatment with BP, there is no immediate increase in remodeling, but rather this increase will appear progressively over time, which implies a stability or slight loss of BMD, while this residual effect lasts longer.

This property of BP justifies the possibility of considering a temporary suspension of treatment or therapeutic vacations in patients with low risk of fracture.

**Discontinuation of DMAB treatment**
DMAB has a reversible RANKL inhibition effect, so that discontinuation of treatment produces a rapid and marked increase in bone remodeling, with elevation of formation and resorption markers, as early as 9 months after the last dose, reached levels even higher than those prior to treatment, and which did not normalize until after 24 months. This “rebound” effect on remodeling is accompanied by a rapid loss of BMD, which can reach the values prior to the start of treatment (figure 1) and, in some patients, an increased risk of vertebral fractures, particularly multiple ones. The incidence of vertebral fractures in women with postmenopausal osteoporosis who discontinue DMAB has been estimated between 8.5-10.5% in the 12-18 months after discontinuation, although some of these fractures could be due not only to the effect “Rebound”, but rather the return to a high-risk situation due to previous vertebral fractures that patients had before starting treatment with DMAB.

A systematic review of the literature carried out by a European Calcified Tissue Society (ECTS) working group demonstrated that the risk factors for the presentation of multiple vertebral fractures in patients who discontinue DMAB are young age, having prevalent vertebral fractures, a duration of treatment greater than 2.5 years, a greater gain in hip BMD during treatment and a greater decrease in hip BMD after discontinuation. Some case series indicate that previous treatment with BP could mitigate the rebound effect of remodeling (lower increase in markers) that occurs after discontinuation with DMAB, although it is not clear whether this attenuation prevents loss of BMD and fractures.

The administration of another potent antiresorptive treatment such as BP in patients who discontinue DMAB appears to have partial efficacy on the rebound effect that occurs. Experts recommend that patients who have received ABDM for less than 2.5 years and are at low risk of fracture can be treated with an oral BP for a minimum of 1-2 years (depending on bone markers and BMD). However, patients who have received DMAB for a longer time, those still at high risk of fracture, or those who cannot tolerate oral BP should receive a dose of ZOL 6 months after the last dose of DMAB, which could be repeated at 3-6 months, depending on the levels of bone markers.

Experts conclude that the indication for DMAB should be carefully assessed, especially in young patients, and that in those who discontinue treatment, a BP should be administered 6 months after the last DMAB injection, while there are no more data from new clinical trials.

Based on the data from the systematic review by Tsourdi et al., we present a practical decision algorithm in patients receiving treatment with DMAB (figure 2). In case an invasive dental procedure is necessary during treatment with DMAB, experts recommend that it be performed after the 5th month from the last dose, and the next dose is administered as soon as the surgical wound has healed.

**Discontinuation of treatment with TPTD and ABL**
Discontinuation of TPTD (and probably ABL) is accompanied by a loss of BMD in the spine and femur in the subsequent 12 months, being more marked in postme-
nopausal women (7.1%) than in men (4.1%). The administration of an antiresorptive after discontinuation of TPTD maintains or even increases BMD.36,37.

ROMO treatment discontinuation

The effect of ROMO on bone remodeling is reversible, and its discontinuation is accompanied by a normalization of training and a "rebound" effect of resorption, which translates into a rapid loss of BMD in both the lumbar spine and the hip. (figure 3)38. The previous administration of ALN seems to mitigate this "rebound" effect and attenuate the loss of BMD.

ANTIRESORPTIVE FOLLOWED BY ANOTHER ANTIRESORPTIVE

The administration of DMAB after having received ALN achieves greater suppression of remodeling and greater gain in BMD than the same treatment time with ALN alone.39 The ALN-DMAB sequence also appears more efficient than the ALN-ZOL sequence, at least in terms of DMO gain.40

Therefore, in patients treated with oral BP who present a therapeutic failure or do not reach the goal of treatment, a reasonable option could be the transition to DMAB or ZOL, as long as its indication is clear and the administration of bone former.

On the other hand, and as mentioned above, in order to minimize the rebound effect that occurs on bone remodeling after discontinuation of DMAB, it seems advisable to administer a BP (oral or intravenous) at 6 months of the last injection of DMAB (figure 2).

ANTIRESORPTIVE FOLLOWED BY OSTEOFORMER

Previous treatment with BP, especially with those with a higher affinity for hydroxyapatite (ALN and ZOL), seems to attenuate the BMD gain that occurs with TPTD, observing a decrease in the first 6 months of treatment, although anti-fracture efficacy seems to be maintained as demonstrated in a post-hoc analysis of the VERO study.43

Figure 1. Changes in bone mineral density of the lumbar spine (A), total hip (B) and 1/3 radius (C) during the 24 months of treatment with denosumab and during the 24 months after discontinuation. (Modified from Bone HG, et al.) 30

Figure 2. Decision algorithm in patients receiving denosumab treatment for osteoporosis. (Adapted from Tsourdi E, et al.) 34

*: if zoledronate is not available, administer an oral bisphosphonate for 1-2 years
However, the transition from RLX to TPTD does not seem to attenuate the osteoforming effect or the BMD gain of the latter. In the DATA-Switch study, the women who received DMAB for 2 years and switched to TPTD presented an increase in bone remodeling, with a marked decrease in BMD in the hip in the first year, but which recovered in the second year, returning to BMD values at the onset of TPTD (figure 4). Although there is no evidence whether this transient loss of BMD is accompanied by an increased risk of fracture, some experts suggest not discontinuing treatment with DMAB if TPTD (or ABL) is to be indicated, that is, combination therapy.

In the STRUCTURE study, it was observed that, as occurs in the transition to TPTD, patients who received ALN and switched to ROMO had a lower increase in BMD than patients who received ROMO without prior antiresorptive treatment. Although anabolic treatment with TPTD or ROMO seems more effective in patients not previously treated with antiresorptive drugs, patients who, despite receiving antiresorptive treatment, present a high risk of fracture, probably obtain a greater benefit with the change to bone-forming treatment, except in the case of DMAB, which seems better to maintain a combination therapy with TPTD.

The DMAB-ROMO sequence could be more favorable, since it has been reported that a second 12-month cycle of ROMO in patients who had received 12 months of DMAB after a first 2-year cycle of ROMO does increase spinal BMD lumbar (2.3%) and maintain hip BMD (figure 5). However, it must be taken into account that...
these results have been extracted from a cohort of only 14 patients, and in whom DMAB had only been administered for one year.

**Osteoformer Followed by Anti-resorptive**

Sequential TPTD-RLX treatment has shown to be beneficial. RLX manages to maintain or even increase the BMD gain achieved with previous treatment with TPTD48. Equally beneficial is the TPTD-BP sequence. The BMD gain achieved with TPTD can be increased if, after its discontinuation, a BP is administered, also maintaining the anti-fracture efficacy49.

But the TPTD-DMAB sequence is probably the one that provides the highest BMD gain (18% in the lumbar spine and 9% in the femoral neck after 2 years of treatment with TPTD followed by another 2 years of treatment with DMAB)44.

Depending on the clinical characteristics of the patient and the risk of fracture, we could select one anti-resorptive or another after completing the two years of treatment with TPTD (figure 6). A study with 68 postmenopausal women has recently been published comparing the efficacy of 3 repeated cycles of 6 months of TPTD followed by 6 months of DMAB (total 36 months), versus a standard treatment of 18 months of TPTD followed by 18 months of DMAB. After 3 years of treatment, the patients who received standard sequential therapy achieved greater gains in BMD in the lumbar spine (16% vs 12%; p=0.04), with no changes in hip and radius BMD. Cyclical therapy achieved better results in hip and radius BMD at 18 months, so according to the authors, repeated cyclical treatment of TPTD and DMAB could be potentially useful in patients at imminent risk of fracture, especially in patients at higher risk of non-vertebral fracture50.

The ABL-BP sequence is also effective. In the extension of the ACTIVE study, the administration of ALN after ABL was shown to increase the BMD gain achieved with ABL and to maintain anti-fracture efficacy51. There are also data on the ROMO-anti-resorptive sequence. In the ARCH study, it was observed how the BMD gain achieved with ROMO was maintained after switching to ALN. Regarding anti-fracture efficacy, the reduction in the risk of vertebral fracture was maintained and the reduction in the risk of non-vertebral fracture was increased52.

In the FRAME study, the sequence 1 year of ROMO followed by 1 year of DMAB was equally beneficial in terms of gain in BMD and reduction of the risk of vertebral fracture. Although a lower incidence of clinical fractures and non-vertebral fractures was also observed with this sequential treatment than with a single year of ABMD, it must be said that the differences were not significant53.

**Therapeutic Holidays**

In order to minimize the risk of long-term complications or improve patient adherence to treatment, a temporary interruption of anti-resorptive treatment may be considered in the management of osteoporosis, but only with BP both oral and intravenous, given its remaining effect on the skeleton54,55,56.

The working group on the management of patients with osteoporosis on prolonged treatment with BP of the American Society for Research in Bone Metabolism (ASBMR) recommends considering therapeutic holidays after at least 5 years of treatment with oral BP or 3 years of ZOL, but only in patients under 70 years of age, without fractures before or during treatment and who do not have a hip BMD in the osteoporosis range or present risk factors for fracture or a high risk according to FRAX57.

The duration of the therapeutic holiday will depend on the BP used, being greater in the case of BP with greater affinity for hydroxyapatite such as ALN (2 years) or ZOL (3 years), and lower (1-2 years) in the case of BP with lower skeletal affinity such as RIS or IBN58.

It should be remembered that a temporary interruption cannot be considered with any other anti-resorptive, and that doing so with DMAB could expose the patient to a situation of high risk of fracture, especially vertebral, especially among patients with a previous vertebral fracture, as already mentioned, previously. It is precisely in these cases that one might ask the reasons for a suspension or interruption of treatment.

**Combination Therapy**

The combination of two anti-resorptives has not been shown to be more effective than treatment with a single anti-resorptive59.

Nor does the combination of osteoformer with BP provide greater efficacy. The combined treatment of TPTD and ALN appears to be even less effective than TPTD alone60. In any case, it could be somewhat more beneficial to add TPTD to treatment already started with BP or to add BP to treatment already started with TPTD61, although more studies are needed to confirm this assumption.

Combined TPTD and ZOL therapy has been shown to achieve a faster increase in BMD in both the lumbar spine and the hip, although with no greater gain in BMD at 12 months than TPTD in monotherapy62.

The most promising combination therapy is the simultaneous administration of TPTD and DMAB. In the DATA-Switch study, it was observed that the patients treated with the combination had greater increases in BMD in the spine and hip than the patients treated with each drug alone (figure 4)63.

According to the latest osteoporosis recommendations of the Spanish Society of Rheumatology, this combination could be justified in very selected cases of severe osteoporosis64.

**Conclusions**

- Osteoporosis is a chronic disease that usually requires treatment for many years.
- For optimal management of the disease, the clinician must know very well the mechanism of action, efficacy and safety of each of the drugs, as well as the differences that exist according to the order of administration of the same.
- With the exception of BPs, which have a residual anti-fracture effect, discontinuation of treatment for osteoporosis is not favorable for the bone, being especially negative in the case of DMAB.
- For this reason, therapeutic holidays can only be considered in patients treated with BP with a low risk of fracture.
- The change from an anti-resorptive to another anti-resorptive with a different mechanism of action is an option that may be favorable in the management of some patients with osteoporosis.
Figure 4. DATA-Switch study. The denosumab-teriparatide sequence produces a marked decrease in bone mineral density in the hip in the first year of transition, which recovers in the second year (red). The teriparatide-denosumab sequence achieves a marked gain in BMD in the hip (blue), similar to the combination therapy followed by denosumab (green). (Adapted from Leder BZ, et al.)

Figure 5. Sequential denosumab-romosozumab treatment after a 2-year cycle of romosozumab succeeds in increasing bone mineral density in the lumbar spine and hip. (Adapted from Kendler DL, et al.)
• Although exchanging an antiresorptive for an osteoformer may be associated with a lower initial BMD gain (or even loss in the case of ABMD), this does not appear to have negative consequences on antifracture efficacy.

• Starting with bone-forming treatment (TPTD or ROMO) and then continuing with an antiresorptive is the best treatment sequence, so it could be the preferred option in patients with a very high risk of fracture.
